To the Editor:

Even though tuberculosis is the major theme on most of the recent articles concerning pulmonary infections published in the Brazilian literature, less common infectious diseases have been described and deserve attention. Studies on parainfluenza virus 3 pneumonia, pulmonary cryptosporidiosis, histoplasmosis, and bird fancier’s lung have been recently published. We would like to highlight another infection that can cause diffuse lung disease and is common in extensive tropical and subtropical regions: malaria, caused by the protozoan Plasmodium sp.

We report the case of a 38-year-old man born in Amazonas, Brazil, who presented with intermittent fever, chills, dyspnea, and hematuria. Laboratory tests detected anemia and transaminase elevation, and a blood smear was positive for Plasmodium falciparum. A chest X-ray showed bilateral pulmonary infiltrates, whereas CT showed interlobular septal thickening, areas of consolidation, and bilateral pleural effusion, suggestive of pulmonary edema (Figure 1). The patient responded well to antimalarial drugs and was discharged from the hospital after 11 days.

Malaria is a vector-borne disease caused by Plasmodium sp. (P. falciparum, P. vivax, P. malariae, and P. ovale), being responsible for a significant global public health problem. Nearly one million people die annually due to complications of the disease, which is endemic in tropical and subtropical regions. The bite of an infected anopheline mosquito transmits the infectious agent into the bloodstream through the invasion of erythrocytes. The parasitized erythrocytes impair perfusion, nutrition, and oxygen delivery in tissues, especially the brain. Infection with P. falciparum may result in potentially lethal complications, including cerebral malaria, acute renal failure, and pulmonary involvement.

Pulmonary manifestations occur in 3-10% of the patients and range from asymptomatic cases to fatal pulmonary edema caused by capillary leakage. Although patients with uncomplicated malaria usually present with fever and nonspecific symptoms, severe and complicated malaria is characterized by multiorgan involvement, including acute lung injury and acute respiratory distress syndrome (ARDS). Pulmonary edema is a major complication of severe malaria, with a high mortality rate. It is often difficult to differentiate between pulmonary edema and ARDS. The development of pulmonary edema in association with malaria characteristically occurs in the absence of cardiac failure or fluid overload.

In patients with acute lung injury/ARDS due to malaria, chest X-rays may reveal bilateral opacities and increased interstitial markings mimicking the pattern observed in patients with ARDS due to other causes. Small pleural effusions may be observed. Pulmonary edema may occur early due to heavy parasitemia or later due to prolonged altered capillary permeability in severe malaria. Malaria is diagnosed parasitologically and is usually confirmed by thick (for parasitemia detection) and thin (for species identification) peripheral blood smear examinations. In patients with severe complicated malaria, the early administration of specific antimalarial therapy is life-saving. Quinine and artemisinin derivatives are currently used for the parenteral treatment of severe complicated malaria.
Plasmodium falciparum malaria: another infection of interest to pulmonologists
